Abstract

Lower urinary tract symptoms form a significant burden for many patients. A key step in management of such patients includes the exclusion of urinary tract infection. In patients with classic symptoms of acute infection including frequency and dysuria history alone is sufficient. However in patients with non-dysuric lower urinary tract symptoms, we rely on commonly used investigations to exclude infection. These tests include the midstream urine culture, microscopy of urinary and urinary dipstick tests. Our understanding of urinary infection has advanced, however the tests we use in clinical practice do not exclude urinary tract infection. This review explores the role and inadequacies in the current tests used to exclude urinary infection in patients that present with urinary infection.

Abbreviations: LUTS: Lower Urinary Tract Symptoms; UTI: Urinary Tract Infection; PPV: Positive Predictive Value; NPV: Negative Predictive Value; CSU : Catheter Specimen of Urine

Review

In patients who present with lower urinary tract symptoms (LUTS) it is important to exclude the presence of bacterial infection which may be responsible for the presenting symptoms. In patients presenting with acute frequency and dysuria, diagnosis is based on history alone. However, in patients presenting without dysuria we rely on investigations to help exclude urinary tract infection (UTI). Internationally and in the UK these include the quantitative clean-catch midstream urine culture, which is used as the gold standard for diagnosis, as recommended by NICE (2015) in the UK. In addition, as recommended by NICE and the International Continence Society (ICS) (2002, 2010) microscopy of urine, bedside testing with urine dipsticks to test for leucocyte esterase and nitrites as well as microbiological culture of urine, is used to test for infection.

Published guidelines across Europe, USA and the UK reveal significant discrepancies in the choice of a quantitative threshold used to define significant bacteriuria. The clean-catch, midstream urine (MSU) sample culture in the UK and Europe commonly uses the Kass (1957) criterion of 10^5 colony forming units (cfu) ml^{-1} of a single species of a known urinary pathogen [1,2]. Kass drew these data from 74 women with acute pyelonephritis and 337 normal controls, a select sample unrepresentative of wider lower urinary

tract symptoms (LUTS). Despite its limitations, this criterion has become a ubiquitous reference standard and has been challenged by several groups [3,4]. The Associate of Urology (EUA) guidelines for urological infections emphasize that no single threshold can be applied in all clinical situations. The dipstick testing has been validated against the Kass criteria. It is now well documented in the literature that the urinary dipstick tests used for bedside testing for nitrite and leucocyte esterase are unreliable [5-8].

The quantitative microbiological bacterial culture remains the reference gold standard in diagnosis of significant bacteria. Currently in the UK the proposed threshold that discriminates normal from pathology is 10^5 cfu ml^{-1} . This threshold is based on the original work by Kass with a positive culture being defined as greater than 10^5 cfu ml^{-1} of a single known urinary pathogen was significant of urinary tract infection in this group of patients. This continues to be used as the threshold that discriminates between normal and 'urinary tract infection' in patients who present with lower urinary tract symptoms, in many centres internationally. There has since been other work in patients presenting with classic symptoms of acute cystitis with sudden onset of pain, frequency and urgency. It was found that a threshold of 10^5 cfu ml^{-1} missed nearly 50% of genuine coliform infections. It was proposed that

in patients with symptoms of acute cystitis, bacterial growth of greater than 10^2 cfu ml⁻¹ of a known urinary pathogen was a more appropriate threshold in this group of patients [3,9]. Unfortunately however much of this work has been overlooked and in patients who present with LUTS, many laboratories still define a positive culture as growth of more than 10^5 cfu ml⁻¹ of a known urinary pathogen.

In clinical medicine, to aid diagnosis we frequently use absolute terms to describe the existence or absence of disease. However nature and biology do not allow such distinct entities and commonly disease manifests across a spectrum [10]. In patients describing symptoms of acute frequency and dysuria the diagnosis of UTI is not challenging and should be based on history alone. However in patients presenting with non-dysuric symptoms we still rely on the use of current investigations to help exclude urinary infection. It is now widely appreciated that in patients with lower urinary tract symptoms, a midstream urine sample that is reported as negative based on the 10^5 cfu μ l⁻¹ threshold does not exclude significant UTI [3,8,11-14]. It is also important to consider that nature works does not present with categories but to consider a continuum.

The work by Kass also only addressed pathogenic coliform organisms, and mixed growth was thought to be likely due to contamination and was dismissed. There is now evidence to support polymicrobial infection in human disease, with work exploring this in the bladder [4]. The culture methods used today also assume dominant pathogenicity from the Enterobacteriaceae species, notably *E. coli*. Because of this assumption, the MSU culture is performed on a selective medium (selective chromogenic medium) for Enterobacteriaceae under aerobic conditions. This does not allow for the growth of anaerobic bacteria and other pathogens, which do not grow well under such culture conditions. Whilst this might be appropriate for diagnosing acute infection, there is no evidence that the same bacteria are implicated in chronic infections or patients presenting with non-dysuric lower urinary tract symptoms such as in the overactive bladder. It is therefore not appropriate to use the current MSU culture for such patients and this is an avenue that warrants further explorations.

Microscopy of urine for the detection of urinary leucocytes is widely used as a surrogate marker of urinary infection. Due to the time, cost and effort of MSU cultures, in some laboratories, microscopy of pyuria acts as a screening tool where only those samples with significant microscopic pyuria are then sent for culture. This technique stems from Dukes work in 1927 which predates Kass' work. His work reviewed midstream urine samples from 300 asymptomatic volunteers and found a mean leucocyte counts of 1.6 wbc μ l⁻¹ in males and 5.4 wbc μ l⁻¹ in females with a range of $0-50$ wbc μ l⁻¹ [15].

From this, he proposed an arbitrary cut off of <10 wbc μ l⁻¹ as the limit for normal pyuria. As a consequence we now use a microscopic pyuria ≥ 10 wbc μ l⁻¹ to suggest urinary infection. The work by Dukes is open to similar criticism to Kass' work of spectrum bias. Here a healthy population has been used to define disease in a symptomatic population. In addition the data from Dukes work

shows a wide range of pyuria and hence the data would be skewed and not normally distributed. Therefore use of the median would have been a more appropriate measure of central tendency and had that occurred, zero pyuria would have been promoted as the normal state. The samples collected in Dukes' work were also voided samples and without careful sampling may be subject to contamination. Studies comparing catheter sampling do not report any differences in leucocyte excretion between the sexes.

Microscopic pyuria is commonly used to exclude infection and many studies have reviewed its performance against quantitative bacterial culture. Some studies have however found that those with symptoms of acute UTI were culture negative, against a threshold of $\geq 10^5$ cfu ml⁻¹ as diagnostic of infection, nearly half demonstrated leucocyte excretion of ≥ 10 wbc μ l⁻¹ [16,17]. These data support pyuria excretion ≤ 10 wbc μ l⁻¹ as a common finding amongst women with acute cystitis symptoms, and questions the microbiological definition of UTI, long before Kass' work was re-evaluated. This history illustrates the error of propositions being accepted as explanatory in the absence of empirical support.

There are limited data evaluating the role of microscopic pyuria as a surrogate marker of infection in patients with non-acute symptoms. In patients with painless LUTS microscopic pyuria has been reported to have a sensitivity of 56% (95% CI 46-60%) and specificity of 72% (95% CI 67-76%) for midstream urine (MSU) cultures at $\geq 10^5$ cfu ml⁻¹, and 66% (95% CI 54-77%) and 73% (95% CI 69-78%) respectively for catheter specimen of urine (CSU) culture at $\geq 10^5$ cfu ml⁻¹ [18]. In patients presenting with non-acute symptoms Kupelian et al. [19] found the positive predictive value (PPV) and negative predictive value (NPV) of pyuria as a surrogate marker of UTI to be 0.40 (CI 0.37-0.43) and 0.75 (CI 0.73-0.76) respectively. They found that 40% of the inflammatory signal was lost by 4 hours after sample collection which is a common delay between patients providing samples and time taken to arrive at laboratories for analysis [19]. Given that microscopy of urine is performed by laboratories so that only those with ≥ 10 wbc μ l⁻¹ require culture samples may be wrongly dismissed as negative for infection.

Urinary dipsticks are commonly used in both primary and secondary care as a bed side test and in point of care testing when excluding urinary infection. They were introduced as part of 'point of care testing' to aid in diagnosis of UTI and reduce the need for urine microscopy and urine culture and allow for earlier treatment. Modern reagent strips are able to provide information on a variety of physical and biochemical variables. The principle measure of UTI includes the presence of leucocyte esterase and nitrites. Leucocyte esterase is a potential measure of pyuria and the Nitrite test uses the Greiss reaction to detect a nitrate reduction product of some uropathogenic bacteria [20]. The International Consultation on Incontinence guidelines on LUTS strongly recommends the need to exclude UTI and recommends dipstick testing as a screening method [21]. NICE also recommends the use of urinary dipstick for screening patients with lower urinary tract symptoms [22]. However, there are no published data to support dipstick as a valid

screening tool for patients with non-acute, non-dysuric symptoms. On reviewing the literature there is considerable evidence to question the accuracy of urinary dipsticks [5,6,23,24]. The sensitivity of leucocyte esterase has been suggested to be around 60% and specificity of around 70%. The sensitivity of nitrite is approximately 18%-50%, with reported specificities of 90% [5,24]. However this is using a gold standard as an MSCU culture with a positive threshold as $\geq 10^5$ cfu ml⁻¹.

In assessing anyone who presents with LUTS a mandatory step is the exclusion of UTI, but given the deficiencies in the tests diagnosis may be flawed. We must therefore be aware of this and take into consideration the potential for infection. This warrants further research into how we identify and exclude infection, as well as re-evaluates the pathophysiology of common urological and urogynaecological conditions.
