Objectives and Introduction

Osteoporosis is a worldwide epidemic, expresses high morbidity and mortality, resulting in high social [1]. Today, the examination of bone densitometry by Dual-energy X-ray absorptiometry (DXA) is the gold standard test for diagnosing the disease. However, its cost and viability are restricted mainly to underdeveloped and emerging countries. The availability of equipment for bone densitometry in Brazil in 2005 was 0.8 per 1 million inhabitants [2,3]. Panoramic radiography has been used to screen patients with low bone mineral density (BMD) evaluating the thickness and shape of the mandibular cortica [4-9]. The fact of panoramic radiograph cover important anatomical structures and have a low cost can be of great value to Dentistry providing the dentist the diagnosis of maxillary bone quality.

The aim of this opinion was consider to the results of a Camargo AJ et al. [10], thesis about the characterization of the mandibular canal walls to assess possible changes caused by osteopenia/osteoporosis, indicating whether or not correlation between mandibular bone quality and systemic bone quality. Camargo AJ et al. [10]. Characterization the mandibular canal walls to evaluate possible changes caused by osteoporosis. Thesis de Master's degree defended in the Post-Graduate Program in Oral Diagnosis of FOU SP, 2013).

Method

The author used in her thesis the methodology employed by Alonso et al. [11] Used the Panoramic radiographs of 52 women, aged over 45 years (56.4±8.4 years) were analyzed and divided into three groups, according to results of the DXA (spine, femur and forearm): Group N (normal group, n=26), group E (n=18) with osteopenia and group O (n=8) with osteoporosis. To characterize the pattern of cortical bone of the mandibular canal was used binary and skeletonized images from panoramic radiographs. The quantity of black pixels of each ROI was accounted.

Results

Significant differences were found between relative amount of black pixels in the region of the branch (R) of the mandibular canal ($p < 0.05$) and the mean true when compared among groups of samples. In regions of the mandibular canal near the mental foramen (MF) and angle (A) statistical tests did not show the significant differences. Statistical analyses showed a significant difference in the average amount relative of black pixels in the region of the branch (R) of the mandibular canal ($p < 0.05$) compared among research groups, using the Tukey test.

Discussion

Until the moment no study has addressed the analysis of cortical mandibular canal as performed in this work despite of several researchers have studied the possibility of the use of panoramic radiography in dentistry as a way of screening patients with low bone mineral density [4-17]. The research was based on counting the number of black pixels obtained from the binarization of clippings radiographic images, which resulted in black pixels and white pixels of these binary images.

The Tukey test indicated that the mean of the group N and group O are significantly different. Thus, in the normal group of the cortical of the mandible canal were more radiopaque and evident (contained more black pixels) than the group with osteoporosis. Therefore the more radiopaque the cortical wall of the CM, the structure is denser and healthier. This significant difference between the groups may be related to the low number of teeth present in women with osteoporosis as the mean found in group N was 18.730 and the group O of 3.075, at consistent with several studies [4-6,13,18,19]. According to Alonso et al visual analysis of the morphological characteristics of the mandibular canal performed by an experienced radiologist had a high sensitivity value (70.4%) when correlated to systemic bone diagnosed by DXA [11].

Xie et al. [20] noted that cortical thickness in the mandible angle decreases with aging and show significant differences between 76 and 86 years of age ($p < 0.05$). The authors found that the resorption in the wall of the CM was more prevalent in individuals with asthma (odds ratio 6.0), with thyroid disease (odds ratio: 3.04), and in individuals with a cortical thickness of the mandible in the region of angle of less than 1mm thickness (odds ratio 2.74) By Camargo AJ et al. [10], and I agree this increased resorption of higher cortical of the canal mandible may be related to dental loss and its proximity to the residual ridge, which stopped receiving stimuli of mastication. In the literature, the authors state that occur significant age-related changes in radiomorphometric indices obtained in different regions of the mandibular cortex (mental index, MI; antegonial index, AI and gonial index, GI) identifying low BMD and evaluating the role of osteoporosis in alterations of these indices, which can occur significantly in women and men [15,21,22].

Conclusion

These results suggest that the mandibular canal suffers action of osteoporosis and the analysis of cortical mandibular canal through the amount of black pixels can be a useful tool in the evaluation of patients with osteoporosis.
