Introduction

In Brazil, a Life expectancy at birth is almost 76 years old. With the increase of the average years lived by Brazilians, can we predict that in the future, gains in this indicator will not come as easily. More intervention will be necessary in the causes of death that affect the elderly, for example the osteoporosis, as well as more investments in prevention and treatment, becoming a public health concern. Osteoporosis is the most common metabolic bone disease, affecting one in two women and one in five men aged above 50 years in the world. It is a skeletal disorder characterized by compromises in bone strength that predisposes individuals to an increased risk of fractures. This change is responsible for the imbalance of the mechanics of the skeleton, increased number of fractures, notably in the spine, femoral neck and distal of the radio. This can also be seen in the maxillomandibular region, most obviously in the mandible, with decreased cortical thinning and inferior mandibular body [1,2]. Dual X-ray absorptiometry (DXA) and quantitative computed tomography (QCT) have been standard evaluation protocols in the assessment of bone mineral densities [3-5].

Rehabilitation through dental implants has been a good alternative for the population worldwide, and this technique is evident in dentistry. The bone quality and bone quantity are factors considered fundamental in the diagnostic evaluation of this rehabilitation procedure to consolidation of the bone-implant interface and that can influence surgical technique. The classification of bone quality proposed by Lekholm & Zarb [6], which is mainly based on the subjective feeling of the surgeon during drilling. So, numerous studies report implant treatment outcome by using other approaches to assess bone tissue before and during implant treatment. To evaluate the bone mineral density of the patient through DXA or HU are methods used before and after procedures to enable correct postoperative results.

The use of Hounsfield units (HUs) from CT scanning to assess regional BMD of the column has recently been studied and the correlations between HU and bone mineral density have been established [7], mainly because they are directly related to tissue attenuation coefficients. The information provided by a simple HU measurement can alert the treating physician to decreased bone quality, which can be useful in both medically and surgically managing these patients with a view to implant procedures. As described by Pickhardt et al. [8], when CT scans are obtained for other clinical indications, they may also be used for "opportunistic screening for osteoporosis" [8]. The Computed tomography (CT) is currently the only diagnostically justifiable imaging technique that allows at least rough conclusion about the structure and density of the jaws bone, for assessing the relative distribution of compact and cancellous bone. Modern radiology imaging software programs allow the calculation of the region of interest (ROI) on CT scans without any additional cost or radiation exposure.

There was a high correlation between CT values and the bone density mineral (DEXA) and can be used in an opportunistic screening system for osteopenia/osteoporosis [5,9]. DEXA can be used in conjunction with the CT to confirm the screening diagnosis, forming a comprehensive screening tool for bone loss from CT images. In this study we propose to evaluate the correlation of the densities jaws and based cervical vertebrae of the Hounsfield scale, found in dental routine scans and correlate their values to identify possible localized or systemic osteoporosis. Our methods were based on Norton & Gamble [10] parameters to classify patients about HU densities.

The cervical vertebrae have an average density (in units of HU) values of 222.02, 257.82 and 393.08 respectively. The mandibular...
condyles we find that on average bone density for the right condyles (RC) of all individuals in the analysis is 291.7 HU and average bone density for left condyle (LC) is 303.49 HU. Maxilla and mandibular regions average bone density is 181.65 HU to 46 tooth and 173.23 HU to 36 tooth, for tooth 13 is 378.10 HU and the tooth 23, 349.44 HU.

Analysis densities (in HU) can classify subjects into two groups. The first group, individuals with local osteoporosis (two or fewer bone densities below 200 HU). In the second group individuals with systemic osteoporosis, 3 or more bone densities below 200HU.

Early diagnosis of osteoporosis by bone density measurements allows proper management of osteoporosis to reduce the risk of fractures and the risk of tooth loss [1,2,11,12]. Bone strength reflects the integration of bone mineral density (BMD) and bone quality. Osteoporosis must be detected and treated early to avoid fragility and fractures [1,2,13].

Computed tomography (CT) is considered the method of choice for study of bone structures, one of its main advantages is three-dimensional information presented in a series of thin slices of the internal structure of the study, where the resulting information does not suffer by superposition anatomical structures [5,14-16]. Tay et al. [5], correlated the values of bone density by dual energy X-ray Absorptiometry (DXA) with the values of the bone densities of CT and concluded that there is a strong correlation between the values assessed by two methods and they can be used together to diagnose osteoporosis. Anderson & Schreiber [9], evaluated 25 patients, mean age of 71.3 years, with DXA and CT of the lumbar spine and was obtained correlation of the values and concluded that there is a strong correlation between the two osteoporosis diagnostic methods, classifying the types of bone as normal, (average density 133HU), osteopenic (average 100.8 HU) and osteoporotic (average of 78.5 HU). Oliveira et al. [17] studied 27 CT maxilla and mandible of patients and assessed the bone densities through two software Dental CT and E-film, regions studied and categorized as type 1 bone above 400HU, type 2 and 3 between 400HU to 200HU, type 4 above 200HU.

The DXA is used to quantify and qualify the bone density in the hip bone, femur, forearm and also when the jaw for evaluation of localized osteoporosis, showing that the disease is systemic by being in various places on the bones of the body [1,4,5,18-20] and CT proved as efficient as the DXA for diagnosis of bone densities in different bones in the body. Lee et al. [18] evaluated the lumbar spine 128 women who had CT and DEXA, the trabecular portion of the L4 vertebra was analyzed and values in HU and BMD were determined and compared, showing a strong correlation between the two methods for osteoporosis diagnosis. In this study, correlated the densities of the jaws with the cervical spine, although little studied, is part of the spine, and found strong correlations when there are low densities in the jaw and spine, thus suggesting a classification of systemic osteoporosis for patients.

So, we could conclude that computed tomography used in dentistry appears to be a means of diagnosing osteoporosis located in the jaw or systemic.
